Background: diatoms and paleoclimatology

Diatoms are a type of phytoplankton -- they are photosynthetic algae that function as primary producers in aquatic ecosystems. Diatoms are at the bottom of the food web: they are consumed by filter feeders, like clams, mussels, and many fish, which are in turn consumed by larger organisms like scavengers and predators and, well, us. As a result, changes in the composition of diatom species in marine ecosystems have ripple effects that can dramatically alter overall community structure in any environment of which marine life forms a part.

Diatoms have glass bodies. As a group of organisms, they display a great diversity of body shapes, and many are quite elaborate. The image below, taken from a Scientific American article, shows a small sample of their shapes and structures.

Because they are made of glass, diatoms preserve extraordinarily well over time. When they die, their bodies sink and form part of the sediment. Due to their abundance, there is a sort of steady rain of diatoms forming part of the sedimentation process, which produces sediment layers that are dense with diatoms.

Sedimentation is a long-term process spanning great stretches of time, and the deeper one looks in sediment, the older the material. Since diatoms are present in high density throughout sedimentation layers, and they preserve so well, it is possible to study their presence over longer time spans -- potentially hundreds of thousands of years.

A branch of paleoclimatology is dedicated to studying changes in biological productivity on geologic time scales, and much research in this area has involved studying the relative abundances of diatoms. In this assignment, you'll do just that on a small scale and work with data from sediment cores taken in the gulf of California at the location indicated on the map:

The data is publicly available:

Barron, J.A., et al. 2005. High Resolution Guaymas Basin Geochemical, Diatom, and Silicoflagellate Data. IGBP PAGES/World Data Center for Paleoclimatology Data Contribution Series # 2005-022. NOAA/NGDC Paleoclimatology Program, Boulder CO, USA.

Assignment objectives

In this assignment, you'll use the exploratory techniques we've been discussing in class to analyze the relative abundances of diatom taxa over a time span of 15,000 years. This will involve practicing the following skills.

Acquaint and tidy

- data import
- handling NaNs
- transforming values
- assessing time resolution

Exploratory analysis of individual variables

- visualizing summary statistics
- density histograms and kernel density estimates
- describing variation

Exploratory analysis of multiple variables

- examining correlation structure
- computing and selecting principal components
- interpreting principal component loadings
- using principal components to visualize multivariate data

Communication and critical thinking

- summarizing results in written form
- suggesting next steps

Collaboration

You are encouraged to collaborate with other students on the labs, but are expected to write up your own work for submission. Copying and pasting others' solutions is considered plaigarism and may result in penalties, depending on severity and extent.

If you choose to work with others, please list their names here.

Your name: Roshan Mehta

Collaborators:

0. Getting acquainted with the diatom data

In this assignment you'll focus less on tidying and more on exploration -- the data you'll work with are already tidy. So, in this initial part, you'll:

- import the data;
- examine its structure to get acquainted; and
- perform some simple preprocessing transformations to facilitate exploratory analysis.

The data are diatom counts sampled from evenly-spaced depths in a sediment core from the gulf of California. In sediment cores, depth correlates with time before the present -- deeper layers are older -- and depths are typically chosen to obtain a desired temporal resolution. The counts were recorded by sampling material from sediment cores at each depth, and examining the sampled material for phytoplankton cells. For each sample, phytoplankton were identified at the taxon level and counts of diatom taxa were recorded along with the total number of phytoplankton cells identified. Thus:

- The observational units are sediment samples.
- The variables are depth (age), diatom abundance counts, and the total number of identified phytoplankton. Age is inferred from radiocarbon.
- One **observation** is made at **each depth** from 0cm (surface) to 13.71 cm.

The table below provides variable descriptions and units for each column in the dataframe.

Variable	Description	Units
Depth	Depth interval location of sampled material in sediment core	Centimeters (cm)
Age	Radiocarbon age	Thousands of years before present (KyrBP)
A_curv	Abundance of Actinocyclus curvatulus	Count (n)
A_octon	Abundance of Actinocyclus octonarius	Count (n)
ActinSpp	Abundance of Actinoptychus species	Count (n)
A_nodul	Abundance of Azpeitia nodulifer	Count (n)
CocsinSpp	Abundance of Coscinodiscus species	Count (n)
CyclotSpp	Abundance of Cyclotella species	Count (n)
Rop_tess	Abundance of Roperia tesselata	Count (n)
StephanSpp	Abundance of Stephanopyxis species	Count (n)
Num.counted	Number of diatoms counted in sample	Count (n)

The cell below imports the data.

In [3]: # import diatom data
 diatoms_raw = pd.read_csv('data/barron-diatoms.csv')
 diatoms_raw.head(5)

Out[3]:		Depth	Age	A_curv	A_octon	ActinSpp	A_nodul	CoscinSpp	CyclotSpp	Rop_tess	StephanSpp	Num.counted
	0	0.00	1.33	5.0	2.0	32	14.0	21	22.0	1.0	1.0	201
	1	0.05	1.37	8.0	2.0	31	16.0	20	16.0	7.0	2.0	200
	2	0.10	1.42	8.0	6.0	33	18.0	29	7.0	1.0	1.0	200
	3	0.15	1.46	11.0	1.0	21	1.0	12	28.0	25.0	3.0	200
	4	0.20	1.51	11.0	1.0	38	3.0	18	24.0	3.0	NaN	300

The data are already in tidy format, because each row is an observation (a set of measurements on one sample of sediment) and each column is a variable (one of age, depth, or counts). However, examine rows 3 and 4. These rows illustrate two noteworthy features of the raw data:

- 1. NaNs are present
- 2. The number of individuals counted in each sample varies by a lot from sample to sample.

Let's address those before conducting initial explorations.

'Missing' values

The NaNs are an artefact of the data recording -- if *no* diatoms in a particular taxa are observed, a - is entered in the table (you can verify this by checking the .csv file). In these cases the value isn't missing, but rather zero. These entries are parsed by pandas as NaNs, but they correspond to a value of 0 (no diatoms observed).

Q0 (a). Filling NaNs

Use .fillna() to replace all NaNs by zeros, and store the result as diatoms_mod1. Store rows 4 and 5 (index, not integer location) of the resulting dataframe as diatoms_mod1_sample and print it out.

(Hint: check the documentation for fill_na().)

```
In [4]: diatoms_mod1 = diatoms_raw.fillna(value=0)
# print rows 4 and 5
diatoms_mod1_sample = diatoms_mod1.loc[4:5]
diatoms_mod1_sample
```

Out[4]:		Depth	Age	A_curv	A_octon	ActinSpp	A_nodul	CoscinSpp	CyclotSpp	Rop_tess	StephanSpp	Num.counted
	4	0.20	1.51	11.0	1.0	38	3.0	18	24.0	3.0	0.0	300
	5	0.25	1.55	4.0	9.0	30	10.0	16	14.0	16.0	0.0	203

```
In [5]: grader.check("q0_a")

Out [5]: q0_a passed! ₩
```

Varying total counts

Since the total number of phytoplankton counted in each sample varies, the raw counts are not directly comparable -- e.g., a count of 18 is actually a different abundance in a sample with 200 individuals counted than in a sample with 300 individuals counted.

For exploratory analysis, you'll want the values to be comparable across rows. This can be achieved by a simple transformation so that the values are relative abundances: proportions of phytoplankton observed from each taxon.

Q0 (b). Counts to proportions

Convert the counts to proportions by dividing by the relevant entry in the Num.counted column. There are a few ways to do this, but here's one approach:

- 1. Set Depth and Age to row indices using <code>.set_index(...)</code> and store the result as <code>diatoms_mod2</code> .
- 2. Store the Num.counted column from diatoms_mod2 as sampsize.
- 3. Use .div(...) to divide entrywise every column in diatoms_mod2 by sampsize and store the result as diatoms_mod3.
- 4. Drop the Num.counted column from diatoms_mod3 and reset the index; store the result as diatoms.

Carry out these steps and print the first four rows of diatoms .

(Hint: careful with the axis = ... argument in .div(...); you may want to look at the documentation.)

```
In [6]: # set depth, age to indices
diatoms_mod2 = diatoms_mod1.set_index(['Depth', 'Age'])

# store sample sizes
sampsize = diatoms_mod2['Num.counted']

# divide
diatoms_mod3 = diatoms_mod2.div(sampsize, axis = 0)

# drop num.counted and reset index
diatoms = diatoms_mod3.drop(columns = 'Num.counted').reset_index()

# print
diatoms
```

```

Now that the data are ready for exploratory analysis, take a moment to think about what the data represent. They are relative abundances over time; essentially, snapshots of the community composition of diatoms over time, and thus information about how ecological community composition changes.

Before diving in, it will be helpful to resolve two matters:

- 1. How far back in time do the data go?
- 2. What is the time resolution of the data?

Q0 (c). Time span

What is the geological time span covered by the data? Compute the minimum and maximum age using <code>.aggregate(...)</code> and store as <code>min_max_age</code>.

Note: This may be a new function for you, but it's simple: it takes as an argument a list of functions that will be applied to the dataframe (columnwise by default). So for example, to get the mean and variance of each column in df, one would use df.aggregate(['mean', 'var']). See the documentation for further examples.

(Remember: age is reported as thousands of years before present, so Age = 2 means 2000 years ago.)

Q0 (d). Time resolution

How are the observations spaced in time?

(i) Make a histogram of the time steps between consecutive sample ages.

Follow these steps:

- 1. Extract the Age column from diatoms, sort the values in ascending order, compute the differences between consecutive rows, and store the result as diffs.
 - Hint: use <code>.sort_values()</code> and <code>.diff()</code>.
 - Notice: that the first difference is NaN, because there is no previous value to compare the first row with. Drop this entry when you store diffs.
- 2. Make a simple count histogram (no need to manually bin or convert to density scale) with bins of width 0.02 (20 years).
 - Label the x axis 'Time step between consecutive sample ages'

```
In [10]: # store differences
diffs = diatoms.loc[:, ['Age']].sort_values(by = 'Age', ascending = True).diff().tail(-1)
# construct histogram
alt.Chart(diffs).mark_bar().encode(
```

```
x = alt.X('Age',
                             bin = alt.Bin(step = 0.02),
                             title = 'Time step between consecutive sample ages'),
                y = 'count()
              180
Out[10]:
                                                                                     •••

                                           0.48
                                                    0.64
                               Time step between consecutive sample ages
```

```
In [11]: grader.check("q0_d_i")

Out[11]: q0_d_i passed! 2
```

(ii) What is the typical time step in years?

The typical time step is 40 years.

1. Exploring diatom taxon abundances

Recall that the first type of exploratory analysis question has to do with exploring variation in each variable; to begin, you'll examine the variation in relative abundance over time for the eight individual taxa.

Here are some initial questions in this spirit that will help you to hone in and develop more focused exploratory questions:

- Which taxa are most and least abundant on average over time?
- Which taxa vary the most over time?

These can be answered by computing simple summary statistics for each column in the diatom data.

Q1 (a). Summary statistics

q1_a passed! 📅

Use <code>_aggregate(...)</code> to find the mean and standard deviation of relative abundances for each taxon. Follow these steps:

- 1. See Q0 (c) for an explanation of aggregate(...).
- 2. Drop the depth and age variables before performing the aggregation.
- 3. Use transpose() to ensure that the table is rendered in long form (8 rows by 2 columns rather than 2 columns by 8 rows).
- 4. Store the result as diatom_summary and print the dataframe.

```
diatom_summary = diatoms.drop(columns = ['Depth', 'Age']).aggregate(['mean','std']).transpose()
# print the dataframe
diatom_summary
Out[12]: mean std
```

```
        Out [12]:
        mean
        std

        A_curv
        0.028989
        0.018602

        A_octon
        0.018257
        0.016465

        ActinSpp
        0.135900
        0.053797

        A_nodul
        0.072940
        0.092677

        CoscinSpp
        0.085925
        0.031795

        CyclotSpp
        0.070366
        0.042423

        Rop_tess
        0.060448
        0.076098

        StephanSpp
        0.002447
        0.007721
```

It will be easier to determine which taxa are most/least abundant and most variable by displaying this information visually.

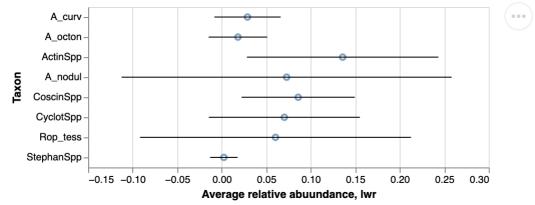

Q1 (b). Visualizing summary statistics

Create a plot of the average relative abundances and their variation over time by following these steps:

- 1. Reset the index of diatom summary so that the taxon names are stored as a column and not an index. Store the result as plot df.
- 2. Create an Altair chart based on plot_df with no marks -- just alt.Chart(...).encode(...) -- and pass the column of taxon names to the Y encoding channel with the title 'Taxon' and sorted in descending order of mean relative abundance. Store the result as base.
 - Hint: alt.Y(..., sort = {'field': 'column', 'order': 'descending'}) will sort the Y channel by 'column' in descending order
- 3. Modify base to create a point plot of the average relative abundances for each taxon; store the result as means.
 - Average relative abundance (the mean you calculated in Q1 (a)) should appear on the x axis, and taxon on the y axis.
 - Since the Y encoding was already specified in base, you do not need to add a Y encoding at this stage.
 - Give the x axis the title 'Average relative abundance'.
- 4. Modify base to create a plot with bars spanning two standard deviations in either direction from the mean. Store the result as bars.
 - First use base.transform_calculate(...) to compute lwr and upr for the positions of the bar endpoints:
 - $lwr = mean 2 \times std$
 - $upr = mean + 2 \times std$.
 - Then append .mark_errorbar().encode(...) to the chain:
 - pass lwr:Q to the X encoding channel with the title 'Average relative abundance' (to match the point plot)
 - pass upr:Q to the X2 encoding channel (no specific title needed).
- 5. Layer the plots: means + bars.

It may help to have a look at this example. Once you make the plot, answer questions (i) - (iii) below.

Out[14]:

(i) Which taxon is most abundant on average over time?

ActinSpp is the most abundant taxon on average over time, since it has the highest average value.

(ii) Which taxon is most rare on average over time?

StephanSpp is the most rare taxon

(iii) Which taxon varies most in relative abundance over time?

A_nodul varies the most in relative abundance over time

Now that you have a sense of the typical abundances for each taxon (measured by means) and the variations in abundance (measured by standard deviations), you'll dig in a bit further and examine the variation in abundance of the most variable taxon.

For the next few questions, it may help you to follow code examples from lab 4.

Q1 (c). Distribution of Azpeitia nodulifer abundance over time

Here you'll construct a few plots that will help you answer the following key exploratory questions:

- Which values are common?
- Which values are rare?
- How spread out are the values?
- Are values spread evenly or irregularly?

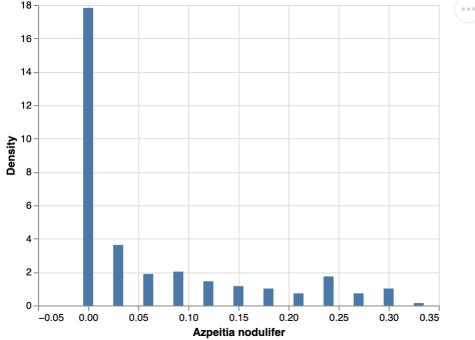

(i) Construct a density scale histogram of the relative abundances of Azpeitia nodulifer.

Use the diatoms dataframe and a bin width of 0.03 and store the histogram as hist.

Hint: It may help to look at Q0 in Lab4 on Smoothing

```
In [15]: #sample_size = len(diatoms)
         \#bin\_width = 3
         #sample_size
In [16]: hist = alt.Chart(
             diatoms
         ).transform_bin(
             'Azpeitia nodulifer',
             field = 'A_nodul',
             bin = alt.Bin(step = 0.03)
         ).transform_aggregate(
                 Count = 'count()',
                 groupby = ['Azpeitia nodulifer']
         ).transform_calculate(
             Density = 'datum.Count/(.03*230)'
         ).mark_bar(size = 10).encode(
             x = 'Azpeitia nodulifer:Q',
             y = 'Density:Q'
         hist
```

Out[16]:

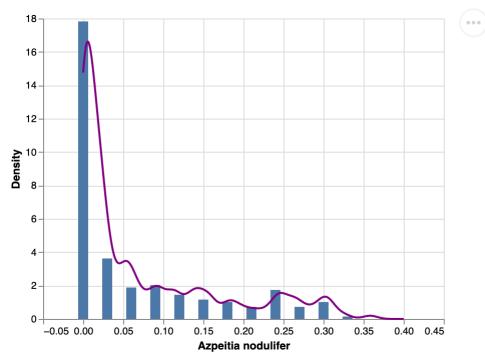

(ii) Construct a kernel density estimate of the distribution.

Create and store the KDE curve as smooth and layer it on top of the density histogram from part i.

(Remember: experiment with the bandwidth parameter, and find a value that you feel captures the shape best.)

```
In [17]:
smooth = alt.Chart(diatoms).transform_density(
    density = 'A_nodul', # variable to smooth
    as_ = ['Azpeitia nodulifer', 'Density'], # names of outputs
    bandwidth = 0.009, # how smooth?
    extent = [0, 0.40], # domain on which the smooth is defined
    steps = 1000 # for plotting: number of points to generate for plotting line
).mark_line(color = 'purple').encode(
    x = alt.X('Azpeitia nodulifer:Q'),
    y = alt.Y('Density:Q')
)
hist + smooth
```

(iii) Which values are common?

Values around 0.00 are the most common.

(iv) Which values are rare?

Values around 0.35 are rare.

(v) How spread out are the values and how are they spread out?

For the different Azpeitia nodulifer values, there are densities for all of them except for 0.35. However, there is a large density bar on the left for 0,00, and the rest are about the same and tend to taper off towards 0.

(vi) How would you describe the shape?

The data looks to be unimodal and is skewed right.

Comment: 'zero inflation'

There are a disproportionately large number of zeroes, because in many samples no *Azpeitia nodulifer* diatoms were observed. This is a common phenomenon in ecological data, and even has a name: it results in a 'zero inflated' distribution of values. The statistician to identify and name the phenomenon was Diane Lambert, whose highly influential work on the subject (>4k citations) was published in 1992.

Zero inflation can present a variety of challenges. You may have noticed, for example, that there was no bandwidth parameter for the KDE curve that both captured the shape of the histogram near zero and away from zero -- it either got the height near zero right but was too wiggly, or got the shape away from zero right but was too low near zero.

Conditioning on a climate event

There was a major climate event during the time span covered by the diatom data. The oldest data points in the diatom data correspond to the end of the Pleistocene epoch (ice age), at which time there was a pronounced warming (Late Glacial Interstadial, 14.7 - 12.9 KyrBP) followed by a return to glacial conditions (Younger Dryas, 12.9 - 11.7 KyrBP).

This fluctuation can be seen from temperature reconstructions. Below is a plot of sea surface temperature reconstructions off the coast of Northern California. Data come from the following source:

Barron et al., 2003. Northern Coastal California High Resolution Holocene/Late Pleistocene Oceanographic Data. IGBP PAGES/World Data Center for Paleoclimatology. Data Contribution Series # 2003-014. NOAA/NGDC Paleoclimatology Program, Boulder CO, USA.

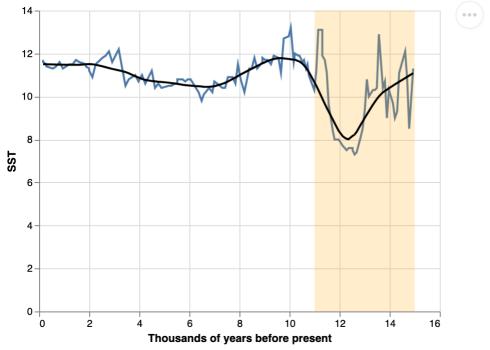

The shaded region indicates the time window with unusually large flucutations in sea surface temperature; this window roughly corresponds to the dates of the climate event.

```
x = alt.X('upr', title = 'Thousands of years before present'),
x2 = 'lwr'
)

# add smooth trend
smooth = line.transform_loess(
    on = 'Age',
    loess = 'SST',
    bandwidth = 0.2
).mark_line(color = 'black')

# layer
line + highlight + smooth
```

Out[18]:

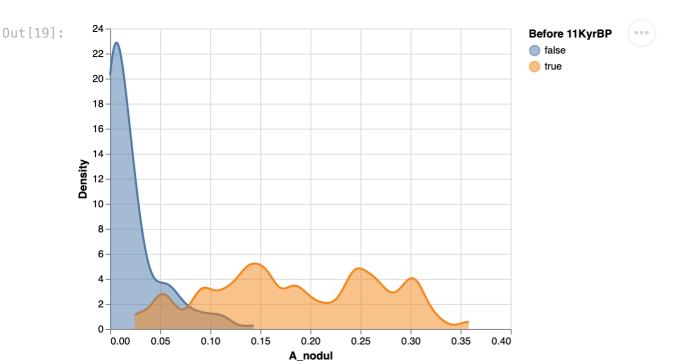

Q1 (d). Conditional distributions of relative abundance

Does the distribution of relative abundance of Azpeitia nodulifer differ when variation in sea temperatures was higher (before 11KyrBP)?

- (i) Plot kernel density estimates to show the distribution of relative abundances before and after 11KyrBP.
- 1. Use .transform_caluculate(...) to calculate an indicator variable, pre_dryas, that indicates whether Age exceeds 11.
- 2. Use transform_density(...) to compute KDEs separately for observations of relative abundance before and after 11KyrBP.
 - *Hint*: group by pre_dryas
- 3. Plot the KDEs distinguished by color; give the color legend the title 'Before 11KyrBP' and store the plot as kdes .
- 4. Add a shaded area beneath the KDE curves. Adjust the opacity of the area to your liking.

```
In [19]: kdes = alt.Chart(diatoms).transform_calculate(
    pre_dryas = 'datum.Age > 11',
    Density = 'datum.Count/(0.03*230)'
).transform_density(
    density = 'A_nodul',
    groupby = ['pre_dryas'],
    as_ = ['A_nodul', 'Density'],
    bandwidth = 0.01,
    #extent = [25, 90],
    steps = 1000
).mark_line().encode(
    x = 'A_nodul:0',
    y = 'Density:0',
    color = alt.Color('pre_dryas:N', legend = alt.Legend(title = 'Before 11KyrBP'))
)
kdes + kdes.mark_area(opacity = 0.5)
```

(ii) Describe the variation in relative abundance of *Azpeitia nodulifer* between now and 11,000 years ago.

The variation in the relative abundace between now and 11,000 years ago is large. It has seen a huge decrease and the data is mainly around 0, and then tapers off.

(iii) Describe the variation in relative abundance of Azpeitia nodulifer between 11,000 and 14,000 years ago.

There is not as much variation n in the data between these years. Compared to the blue density, the orage one is a bit more stable and does not see insanely huge fluctuations. There is some variation in the density for the different times, but it is relatively stable.

2. Visualizing community composition with PCA

So far you've seen that the abundances of one taxon -- *Azpeitia nodulifer* -- change markedly before and after a shift in climate conditions. In this part you'll use PCA to explore variation in community composition *among* all eight taxa.

Throughout this part, it may help you to refer to code examples from lab 5.

Q2 (a). Pairwise correlations in relative abundances

Before carrying out PCA it is a good idea to inspect the correlations between relative abundances directly. Here you'll compute and then visualize the correlation matrix.

(i) Compute the pairwise correlations between relative abundances.

Be sure to remove or set to indices the Depth and Age variables before computing the correlation matrix. Save the matrix as corr_mx and print the result.

Hint: See the pandas documentation for .corr().

In [20]: corr_mx = diatoms.drop(columns = ['Depth', 'Age']).corr()
corr_mx

Out[20]:

		A_curv	A_octon	ActinSpp	A_nodui	CoscinSpp	СусіотSpp	Rop_tess	StepnanSpp

	StephanSpp	0.151909	-0.041017	0.058494	-0.151409	-0.016332	0.070684	0.032607	1.000000

In [21]: grader.check("q2_a_i")

Out[21]:

q2_a_i passed! 🍀

(ii) Visualize the correlation matrix as a heatmap

Have a look at either lab 5 or this example (or both!). Notice that to make a heatmap of a matrix, you'll need to melt it into long format.

- 1. Melt corr_mx to obtain a dataframe with three columns:
 - row , which contains the values of the index of corr_mx (taxon names);

- column, which contains the names of the columns of corr_mx (also taxon names); and
- Correlation , which contains the values of corr_mx .

Store the result as corr_mx_long.

- 2. Create an Altair chart based on corr_mx_long and construct the heatmap by following the examples indicated above.
 - Adjust the color scheme to **blueorange** over the extent (-1, 1) to obtain a diverging color gradient where a correlation of zero is blank (white).
 - Adjust the color legend to indicate the color values corresponding to correlations of 1, 0.5, 0, -0.5, and -1.
 - Sort the rows and columns in ascending order of correlation.

```
In [22]: # melt corr_mx
          corr_mx_long = corr_mx.reset_index().rename(
               columns = {'index': 'row'}
           ).melt(
               id_vars = 'row',
               var_name = 'col',
               value_name = 'Correlation'
          # construct plot
          alt.Chart(corr_mx_long).mark_rect().encode(
               x = alt.X('col', title = '', sort = {'field': 'Correlation', 'order': 'ascending'}),
y = alt.Y('row', title = '', sort = {'field': 'Correlation', 'order': 'ascending'}),
               color = alt.Color('Correlation',
                                    scale = alt.Scale(scheme = 'blueorange', # diverging gradient
                                                         domain = (-1, 1), # ensure white = 0
                                                         type = 'sqrt'), # adjust gradient scale
                                   legend = alt.Legend(tickCount = 5)) # add ticks to colorbar at 0.5 for reference
           ).properties(width = 300, height = 300)
```

Correlation
1.0

Rop_tess A_curv CyclotSpp ActinSpp A_octon StephanSpp StephanSpp
StephanSpp
Rop_tess A_curv CyclotSp A_octon StephanSpp
Rop_tess A_curv A_octon StephanSpp
Rop_tess Rop_tess A_curv A_octon StephanSpp Rop_tess -

(iii) How does the relative abundance of Azpeitia nodulifer seem to covary with the other taxa?

A_nodul has very negative corrlation with Rop_tess, A_curv, and CyclotSpp. There is almost no correlation with CoscinSpp, and there are no variables that it is positively correlated with.

Q2 (b). Computing and selecting principal components

Here you'll perform all of the calculations involved in PCA and check the variance ratios to select an appropriate number of principal components. The parts of this question correspond to the individual steps in this process.

(i) Center and scale the data columns.

For PCA it is usually recommended to center and scale the data; set Depth and Age as indices and center and scale the relative abundances. Store the normalized result as pcdata.

```
In [24]: # helper variable pcdata_raw; set Depth and Age as indices
    pcdata_raw = diatoms.set_index(['Depth','Age'])

# center and scale the relative abundances
    pcdata = (pcdata_raw - pcdata_raw.mean())/pcdata_raw.std()
In [25]: grader.check("q2_b_i")
```

Out [25]: **q2_b_i** passed!

q2_a_ii passed! 💅

(ii) Compute the principal components.

Compute all 8 principal components. (For this part you do not need to show any specific output.)

(iii) Examine the variance ratios.

q2_b_ii passed! 📅

Create a dataframe called pcvars with the variance information by following these steps:

- 1. Store the proportion of variance explained (called .explained_variance_ratio_ in the PCA output) as a dataframe named pcvars with just one column named Proportion of variance explained.
- 2. Add a column named Component to pcvars with the integers 1 through 8 as values (indicating the component number).
- 3. Add a column named Cumulative variance explained to povars that is the cumulative sum of Proportion of variance explained.
 - Hint: slice the Proportion of variance explained column and use .cumsum(axis = ...).

Print the dataframe pcvars.

Out[28]:

Proportion of variance explained Component Cumulative variance explained 0 0.255513 1 0.255513 0.223354 2 0.478867 1 2 0.132145 3 0.611012 3 0.122549 4 0.733560 0.844394 4 0.110833 5 5 0.077988 6 0.922382 6 0.067303 7 0.989684 8 1.000000 7 0.010316

```
In [29]: grader.check("q2_b_iii")

Out[29]: q2_b_iii passed! \( \text{$\frac{1}{2}} \)
```

(iv) Plot the variance explained by each PC.

Use pcvars to construct a dual-axis plot showing the proportion of variance explained (left y axis) and cumulative variance explained (right y axis) as a function of component number (x axis), with points indicating the variance ratios and lines connecting the points.

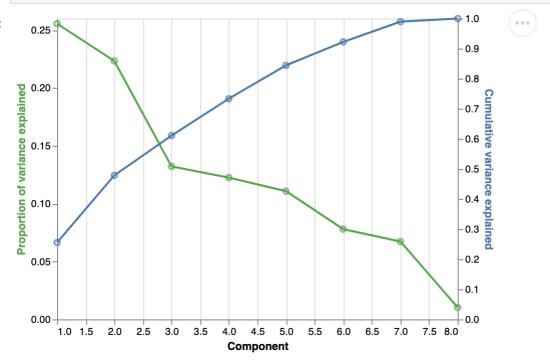

Follow these steps:

- 2. Make a base layer for the proportion of variance explained that modifies base by encoding Proportion of variance explained on the Y channel. Store the result as prop_var_base.
 - Give the Y axis title a distinct color of your choosing via alt.Y(..., axis = alt.Axis(titleColor = ...)).
- 3. Make a base layer for the cumulative variance explained that modifies base by endocing Cumulative variance explained on the Y channel. Store the result as cum_var_base.
 - Give the Y axis title another distinct color of your choosing via alt.Y(..., axis = alt.Axis(titleColor = ...)).
- 4. Create a plot layer for the proportion of variance explained by combining points (prop_var_base.mark_point()) with lines (prop_var_base.mark_line()). Store the result as prop_var.

- Apply the color you chose for the axis title to the points and lines.
- 5. Repeat the previous step for the cumulative variance explained. Store the result as cum_var.
 - Apply the color you chose for the axis title to the points and lines.
- 6. Layer the plots together using alt.layer(l1, l2).resolve_scale(y = 'independent').

```
In [30]: # encode component axis only as base layer
         base = alt.Chart(pcvars).encode(
             x = 'Component')
         # make a base layer for the proportion of variance explained
         prop_var_base = base.encode(
             y = alt.Y('Proportion of variance explained',
                       axis = alt.Axis(titleColor = '#57A44C'))
         # make a base layer for the cumulative variance explained
         cum var base = base.encode(
             y = alt.Y('Cumulative variance explained', axis = alt.Axis(titleColor = '#5276A7'))
         # add points and lines to each base layer
         prop_var = prop_var_base.mark_line(stroke = '#57A44C') + prop_var_base.mark_point(color = '#57A44C')
         cum_var = cum_var_base.mark_line() + cum_var_base.mark_point()
         # layer the layers
         var_explained_plot = alt.layer(prop_var, cum_var).resolve_scale(y = 'independent')
         var_explained_plot
```

Out[30]:

(v) How many PCs?

How many principal components capture a high proportion of covariation in relative abundances? How much total variation do these explain together?

3 components capture a high proportion of covariation in the relatve abundances. These explain a total of around 52% of the total variation. After the 3rd component, we see a semi-flat green line, meaning that not much variation is captured beyond the 3rd pc.

Q2 (c). Interpreting component loadings

Now that you've performed the calculations for PCA, you can move on to the fun part: figuring out what they say about the data!

The first step in this process is to examine the loadings. Each principal component is a linear combination of the relative abundances by taxon, and the loadings tell you *how* that combination is formed; the loadings are the linear combination coefficients, and thus correspond to the weight of each taxon in the corresponding principal component. Some useful points to keep in mind:

- a high loading value (negative or positive) indicates that a variable strongly influences the principal component;
- a negative loading value indicates that
 - increases in the value of a variable decrease the value of the principal component
 - and decreases in the value of a variable *increase* the value of the principal component;
- a positive loading value indicates that
 - increases in the value of a variable *increase* the value of the principal component
 - and decreases in the value of a variable decrease the value of the principal component;
- similar loadings between two or more variables indicate that the principal component reflects their average;
- divergent loadings between two sets of variables indicates that the principal component reflects their difference.

(i) Extract the loadings from pca.

Store the loadings for the first two principal components (called .components_ in the PCA output) in a dataframe named loading_df. Name the columns PC1 and PC2, and append a column Taxon with the corresponding variable names, and print the resulting dataframe.

```
PC2
                  PC1
Out[31]:

(ii) Loading plots

Construct a line-and-point plot connecting the loadings of the first two principal components. Display the value of the loading on the y axis and the taxa names on the x axis, and show points indicating the loading values. Distinguish the PC's by color, and add lines connecting the loading values for each principal component.

Hint: you will need to first melt loading_df to long form with three columns -- the taxon name, the principal component (1 or 2), and the value of the loading.

```
In [33]: # melt from wide to long
         loading_plot_df = loading_df.melt(
             id_vars = 'taxon',
             var_name = 'Principal Component',
             value_name = 'Loading'
         loading_plot_df['zero'] = np.repeat(0, len(loading_plot_df))
         # create base layer with encoding
         base = alt.Chart(loading_plot_df)
         loadings = base.mark_line(point = True).encode(
             y = alt.Y('Loading', title = ''),
             x = 'taxon',
             color = 'Principal Component'
         # store horizontal line at zero
         rule = base.mark_rule().encode(y = alt.Y('zero', title = 'Loading'), size = alt.value(0.05))
         # layer points + lines + rule to construct loading plot
         loading_plot = (loadings + rule).properties(width = 120)
         # show
         loading_plot
```

Out[33]:

(iii) Interpret the first principal component.

Indicate the following:

- which taxa are up-weighted and which are down-weighted;
- how you would describe the principal component in context (e.g., average abundance among a group, differences in abundances, etc.);
- and how you would interpret a positive value of the PC versus a negative value of the PC in terms of diatom community composition.

In the first PC, (blue) the A_nodul taxon is up-weighted. A_curv, ActinSpp, and CyclotSpp are down-weighted. PC 1 is predominantly (but not entirely) a representation of A_nodul and A_curv. If there is lower-than-average A_nodul and higher-than-average A_curv, and a smaller value for PC1 if they have higher-than-average A_nodul and lower-than-average A_curv.

(iv) Interpret the second principal component.

Indicate the following:

- · which taxa are up-weighted and which are down-weighted;
- how you would describe the principal component in context (e.g., average abundance among a group, differences in abundances, etc.);
- and how you would interpret a positive value of the PC versus a negative value of the PC in terms of diatom community composition.

In the second PC, (orange) the CyclotSpp, Rop_tess, and StephanSpp are up-weighted. ActinSpp and CoscinSpp are down-weighted. PC2 is predominantly a representation of Rop_tess and CoscinSpp. If there is lower-than-average Rop_tess and higher-than-average CoscinSpp, and a smaller value for PC1 if they have higher-than-average Rop_tess and lower-than-average CoscinSpp.

Q2 (d). Visualizing community composition

Take a moment to recall that there was a shift in the *A. nodulifer* abundance before and after around 11,000 years ago, which roughly corresponded to a major transition in the earth's climate.

Well, you can now use PCA to investigate whether not just individual abundances but *community composition* may have shifted around that time. To that end, let's think of the principal components as 'community composition indices':

- consider PC1 a nodulifer/non-nodulifer community composition index; and
- consider PC2 a complex community composition index.

A pattern of variation or covariation in the principal components can be thought of as reflecting a particular ecological community composition dynamic -- a way that community composition varies throughout time. Here you'll look for distinct patterns of variation/covariation before and after 11,000 years ago via an exploratory plot of the principal components.

(i) Project the centered and scaled data onto the first two component directions.

This sounds a little more complicated than it is -- all that means is compute the values of the principal components for each data point.

Create a dataframe called projected_data containing just the first two principal components as two columns named PC1 and PC2, and two additional columns with the Age and Depth variables.

Print the first four rows of projected_data .

```
In [34]: # project pcdata onto first two components; store as data frame
projected_data = pd.DataFrame(pca.fit_transform(pcdata)).iloc[:, 0:2].rename(columns = {0: 'PC1', 1: 'PC2'})

# add depth and age to projected data
projected_data[['Depth','Age']] = diatoms[['Depth','Age']]

# print first four rows
projected_data.head(4)
```

```
        Out [34]:
        PC1
        PC2
        Depth
        Age

        0
        -0.294522
        -0.633176
        0.00
        1.33

        -1.771066
        1.637274
        0.15
        1.46
```

```
In [35]: grader.check("q2_d_i")
```

Out[35]:

q2_d_i passed! 📅

(ii) Construct a scatterplot of PC1 and PC2 by age indicator.

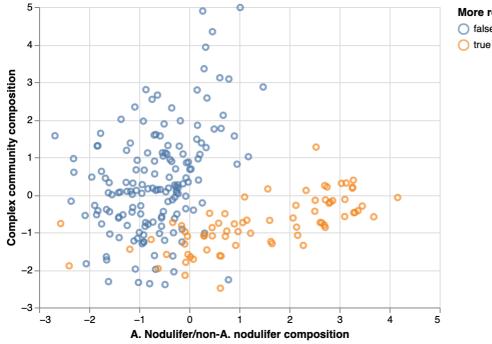

Follow these steps to construct a scatterplot of the principal components.

- 1. Create an Altair chart based on projected_data and use .transform_calculate(...) to define a variable since_11KyrBP that indicates whether Age is older than 11,000 years. Store the result as base.
- 2. Modify base to add points with the following encodings.
 - Pass PC1 to the X encoding channel and title the axis 'A. Nodulifer/non-A. nodulifer composition'.
 - Pass PC2 to the Y encoding channel and title the axis 'Complex community composition'.
 - Pass the variable you created in step 1. to the color encoding channel and title it 'More recent than 11KyrBP'.

Store the result as scatter .

Show the scatterplot once you complete these steps.

More recent than 11KyrBP or false

3. Communicating results

Take a moment to review and reflect on the results of your analysis in the previous parts. Think about how you would describe succinctly what you've learned from the diatom data.

Q3 (a). Summary

Write a brief paragraph (3-5 sentences) that addresses the following questions by referring to your final plot in Q2 (d).

- How would you characterize the typical ecological community composition of diatom taxa before and after 11,000 years ago?
 - Hint: focus on the side and top panels and the typical values of each index in the two time periods.
- Does the variation in ecological community composition over time seem to differ before and after 11,000 years ago?
 - *Hint*: focus on the shape of data scatter.

The typical ecological community composition of diatom taxa data before 11,000 years ago contained much more complex communities, and there was a lot more variation within them. We can see that for the blue values, they tend to go much higher than those of the orange ones which represent the communities after 11,000 years ago. There is also a much bigger range for the blue ones, further indicating that there was a lot more different types of ecological communities that could be found. As such, the variation in the community composition does indeed seem to differ between the two time periods. The orange values seem to stay in a different range of values, and seem to go more horizontal, while the blue goes a bit more vertical. This indicates that there was less complex communities and more of the same ones found more often. There aren't any very high values which is different than the blue.

Q3 (b). Further work

What more might you like to know, given what you've learned? Pose a question that your exploratory analysis raises for you.

Answer

We might want to know what this looked like in more detail, or for different taxa in different time periods. I might also want to know how this affected different areas of the ecological ecosystems.

Submission Checklist

- 1. Save file to confirm all changes are on disk
- 2. Run Kernel > Restart & Run All to execute all code from top to bottom
- 3. Save file again to write any new output to disk
- 4. Select File > Download as > HTML.
- 5. Open in Google Chrome and print to PDF on A3 paper in portrait orientation.
- 6. Submit to Gradescope

To double-check your work, the cell below will rerun all of the autograder tests.

```
In [37]: grader.check_all()
